DESIGN OF A 200 HORSEPOWER AERONAUTICAL ENGINE

A THESIS

PRESENTED BY

P. E. WINKLESS, G. E. O. PETERSON AND C. F. PETERSON

TO THE

PRESIDENT AND FACULTY

OF

ARMOUR INSTITUTE OF TECHNOLOGY

FOR THE DEGREE OF

BACHELOR OF SCIENCE

IN

MECHANICAL ENGINEERING

MAY 27, 1920

APPROVED:

Professor of Mechanical Engineering

Dean of Engineering Studies

Dean of Cultural Studies

Foreword.

The individual who is not thoroughly conversant with the great improvement that has been made in motor car engines, will have difficulty in appreciating how the great capacity per unit of mass of the light motors designed especially for aerial work is largely possible through experience gained in the automobile engineering field. When aeroplanes were first devised numerous unconventional forms of internal combustion engines were contrived that were believed to have features making them specially suitable for the propulsion of aircraft.

At present there are scores of aeronautical engines, each having its own peculiarities of design; but all following the same general plan. Consequently, in the preparation of this work it was considered logical to follow standard practice rather than deviate from the present designs.

It is hoped that interest in aeronautical engineering will steadily increase to such extent that further developement will result in time to

come.

The writers desire to acknowledge their special indebtedness to Professor Daniel Roesch for valuable information and suggestions.

OBJECT.

The object of this work was primarily to design the important members of an experimental six cylinder aeronautical engine capable of delivering 200 horsepower at the normal speed of 1750 R.P.M.

The writers, at the outset, realized that the perfection of the aeronautical engine is a matter of exhaustive testing and redesigning and have undertaken the problem with the idea of acquainting themselves with the difficulties encountered by designers of that type of engine.

Preliminary Considerations.

The problem of the airplane engine should appeal strongly to every engineer because it is a problem of the lightest power plant. The lightest weight of engine proper per horse-power is to be secured first by obtaining maximum mean effective pressure at maximum speed and second by making the weight of metal per cylinder, or per cubic inch of cylinder displacement per working stroke, a minimum. With both these factors in view, the engine must be reliable in operation.

Considering the effect of cylinder diameter upon unit metal weight, it appears that from the unit weight standpoint the cylinder diameter should be as large as possible, because the wall thickness of a cylinder is always greater than necessary for the stress due to structural reasons. This being the case, the larger the cylinder per cubic foot of displacement the less the unit metal weight in the wall, and the only limit to

large cylinder diameter is good operation.

As the stroke is increased, the metal in the cylinder piles up endwise, too fast with reference to volume, and therefore for minimum unit metal weight, the shorter the stroke the better. For that reason as a general thing shorter strokes are used on airplane engines than on automobile engines.

The connecting rod length considerably affects the weight. Clearly, the shorter the connecting rod the shorter the frame, and therefore saving in metal. But, on the other hand by decreasing the length we increase the angularity, which introduces stresses requiring metal thickening in other places.

The number of cylinders should be as large as possible up to the point where the weight of the connecting parts has to be increased. A two cylinder engine has less than twice the weight per cubic foot of displacement than a single-cylinder, for the reason that the number

of end supports for the shaft, etc, is not in-

creased. Similarly a three-cylinder has less

than three times, a four-cylinder less than four

times, and so on; and the weight per cubic foot

of displacement becomes less and less until a

certain number of cylinders (about six) is reached

where the shaft diameter and the weight of the

frame must be increased so as to retain the

necessary stiffness, whereupon the saving in

weight by multiplication is neutralized.

Another method which helps reduce weight is

by overrunning the piston at the lower end of

the stroke. The effect on weight is clearly

seen in that the overall height of the motor is

reduced. Except in special cases where the de-

signer finds it advisable to place a ring at the

open end of the piston, the latter may overrun

the bore close to 1/6 its length.

We may make use of the piston to reduce

weight by another method; namely, by making it

convex outwardly. When a high compression

ratio is desired this helps to reduce the com-
pression volume and thereby reduce the height of
the cylinder. A convex piston head approaches
the spherical form and is therefore strengthened.
On the other hand, however, it has greater area
exposed to the heat; and since the head is not
provided with any cooling means this is a matter
of considerable moment.

Another idea which may or may not have any-
thing to do with the reduction of weight is in
the method of locking the piston pin to prevent
it from scoring the cylinder wall. Some design-
ers favor the use of a single set screw in one
boss of the piston while others place a piston
ring directly over the center of the piston pin.
The latter method has the advantage in that it
allows a full floating piston pin which is de-
sired. The Liberty engine uses aluminum caps
over the ends of the piston pin. A new idea
brought out and at present little used is in pla-
cing a steel spring ring in a groove on either

side of the piston pin. This construction is
favored in the present design chiefly because
of its simplicity and its effect on the reduc-
tion of weight.

The weight of an engine is also a function
of the vertical drive shaft speed. The magnetos
for a six cylinder vertical engine should be run
at 1.5 crankshaft speed. Should the vertical
shaft be run at crankshaft speed the magnetos
must of course be geared up. The housing must
therefore be increased in size and an increase at
this point means that the whole vertical drive
must be moved outward with the resulting increase
in weight. By running the vertical shaft at 1.5
engine speed the above difficulty is overcome and
in addition, the increase in speed results in the
decrease in torque and the shaft may be made
lighter.

General Description.

(A) Cylinders.

The cylinders are steel sleeves made from pierced forgings similar to high explosive and shrapnel shells. These are solid at the upper end and the valve seats are formed directly in the bottom of the cylinder itself. The outside of the cylinder is threaded, and screws into an aluminum casting which looks like a cylinder block but is in reality only the water jacket for all six cylinders of the block. The lower ends of the cylinder sleeves project and have flanges fastening the cylinder block to the engine base by means of triangular bridge clamps; the latter being held in place by $\frac{1}{2}$ inch rods which extend through holes in the webs of the two halves of the crankcase. The individual cylinder sleeves are heat treated, machined and threaded on the outside. The cylinders are screwed into the cast aluminum cylinder block

which comprises the water jackets and valve ports, intake and exhaust passages.

(B) Valves and valve gear.

As is before stated, the valves are located in the heads of the cylinder sleeves. They are set vertically in the cylinders along the center of each block and are directly operated by a single camshaft located over the valves. The valves are of chrome-nickel steel, with large diameter hollow stems, working in tight fitting cast iron bushings, provided at the upper ends with case hardened flat headed adjusting discs, upon which the cams operate and are held to their seats by single helical springs. The hollow camshaft is mounted in four plain bronze bearings and is driven from the crankshaft by a vertical shaft and bevel gears of hardened alloy steel. This vertical shaft which runs at 1.5 crankshaft speed is mounted in two combined radial and thrust ball bearings located

at and near the lower end, and in a plain bear-
ing at its top end. Directly above the inter-
mediate ball bearing this shaft carries a bevel
pinion which meshes with two other bevel pinions
of the same size as itself. The latter pinions,
which are mounted on a common axis, drive the
two Dixie high-tension magnetos, located on oppo-
site sides of the vertical shaft. The upper
part of the vertical shaft is inclosed in a
housing of light steel tubing and the lower part
in an aluminum housing, the upper end of which
is large enough to allow the intermediate radial
ball bearing to be put into place. The bevel
gears for the magnetos are mounted directly on
the shafts of these devises and no extra bear-
ings are required in the housing. Light steel
caps are screwed into the housing over the mag-
neto shafts, back of the driving gears and are
provided with felt washers to keep out the dust
and keep in the oil spray. The hollow camshaft

has an outside diameter of $1\frac{3}{8}$ inches and an in-

side diameter of $1\frac{1}{8}$ inches. At the forward

end it is provided with an eight tooth spline

upon which is mounted the camshaft driving gear.

The gear is held in place by a lock nut which

is prevented from coming loose by a steel pin.

The cams are forged integral with the camshaft,

cut and ground to size and hardened. The valves

have a lift of $\frac{3}{8}$ in. and have a clear opening of

$2\frac{1}{8}$ in. The valve discs are adjusted to give a

.02 in. clearance when the engine is cold. From

the forward end of the camshaft a speedometer

drive is taken off.

(C) Pistons.

Die cast aluminum pistons are employed. These

are of unusual design in that the piston head and

a considerable portion of the skirt are about $\frac{1}{2}$ in.

thick, the object in using such heavy walls being,

of course, to facilitate the flow of heat from the

head to the skirt. Each piston is cut with grooves

for three compression rings near the top end.
Depressions are formed on the piston surface
where the bosses are located, so that any slight
distortion of the bosses will not affect the
bearing of the piston in the cylinder. Each
piston was estimated to weigh between 3 and 4
lbs. when finished. There are no ribs inside
the piston to strengthen the bosses and help to
conduct away the heat, these being rendered un-
necessary by the heavy wall thickness employed.
The bosses are very firmly secured to the skirt,
however, by large fillets; in fact, the bosses
really form solid segments inside the cylindri-
cal skirts. The piston pin is full floating and
is prevented from scoring the cylinder wall by
two steel spring rings which fit into grooves in
the piston bushings. All of that part of the
skirt not occupied by ring grooves has oil grooves
cut upon it. The skirt wall is tapered from
about the axis of the piston pin to the open end,

while the head is plain. Over the whole length
of the skirt the piston is finished up to .02 in.
below the nominal cylinder bore, while on the
lands, it is finished to diameters which are .025,
.030, and .035 in. below the cylinder bore re-
spectively.

(D) Connecting rods.

The connecting rods are tubular and are
machined all over from a steel forging. The out-
side diameter of the tubular rod is $1\frac{1}{8}$ in. and
the inside is bored with a $\frac{27}{32}$ in. hole from the
crankpin end to within $\frac{3}{16}$ in. of the wrist pin
busing. The bottom end of the bore is fitted
with a screwed plug. The weight of the big end
is lightened by holes drilled radially through
the big end. Two semi-circular oil grooves are
machined in the babbitt metal of the big end
bearing cap and a circular groove is cut in the
wrist pin bushing for lubrication. The bronze
wrist pin bushing is forced into the rod and is

broached out to a diameter of $1\frac{1}{4}$ in. The con-
necting rod cap is held in place by four $\frac{3}{8}$ inch
bolts with castellated nuts and split pins.
The bore of the big end of the connecting rod is
2 inches and the length of the crankpin bearing
is $2\frac{1}{2}$ inches. All the connecting rods are bal-
anced by weighing, the limits being $\pm\frac{1}{4}$ oz.
(E) Crankshaft.

A seven bearing crankshaft is used, having
main journals $2\frac{3}{16}$ inches in diameter. All in-
termediate bearings are $2\frac{1}{16}$ inches long. The
forward end bearing is $2\frac{1}{4}$ inches long and the
rear end bearing $4\frac{3}{4}$ inches. Three-quarter inch
holes are drilled through all of the journals of
the crankshaft with the object of lightening it,
and also in the case of the crankpins, to help
in the lubrication. To a forged flange at the
forward end of the crankshaft is bolted the crank-
shaft gear. The crankshaft is a chrome nickel
steel forging and is machined all over. It is

provided with a thrust collar to the rear of the
rear bearing, back of which is mounted a double
ball thrust bearing. The propeller hub seat is
turned to a taper and cut with a keyway. The
crankshaft being made of alloy steel is, of course,
heat treated.

(F) Crankcase.

The crankcase is in two pieces, both of
which are aluminum castings. The crankshaft bear-
ings are on a line with the split in the crankcase,
the lower halves of the crankshaft bearings being
held in the lower half of the crankcase and the
upper halves in the upper half of the crankcase.
The two halves are tied together by long bolts
which pass through the upper half of the crankcase,
through bosses, and clamp the cylinder sleeves in
place as before described. This gives an accessible
construction which is at the same time rigid. A
careful joint is made between the two halves of the
crankcase in order to secure the desired alignment

at the main bearings, the joint being lapped.

(G) Lubrication.

The oil supply is carried in a reservoir which is cooled. This reservoir is mounted somewhere in the vicinity of the engine and from it oil is led to the connection on the right side of the oil pump body, which is to be marked "Oil In". The oil is filtered at this point through a large-area, fine mesh screen. A delivery pump of the gear type takes the oil after it has passed through the screen and delivers it under pressure to a distributor pipe running the entire length of the crankcase. There is a pressure regulating valve between the pump and the distributing pipe which should hold the oil pressure so that it does not exceed 50# per sq. inch.

From the distributor pipe there are pipes fitted in the crankcase leading to the main crankshaft bushings. The crankshaft is hollow,

and in the center of each main bearing there is
a radial hole drilled through the shaft into the
hollow center. A passage leads from each hollow
main bearing to the adjacent crankpin, which is
also hollow. A radial hole is drilled through
each crankpin and carries the oil out on the sur-
face of the pin.

The oil spray thrown off by centrifugal
force from the ends of the connecting rods lubri-
cate the piston pins and cylinder walls. A part
of the oil from the main distributor pipe at the
propeller end of the engine goes up through a
pipe that leads to the propeller end camshaft
bearing. The oil is lead through a passage drilled
diametrically through the bearing midway of its
length. Once every revolution of the camshaft, a
hole drilled through the camshaft, into its hollow
center registers with the oil passage through the
bearing. Thus, once every revolution of the cam-
shaft a small quantity of oil is forced into the

hollow center. The oil is led through the camshaft and out through holes drilled in it to each camshaft bearing. A small hole is drilled in the base circle of each cam to properly lubricate the tappet. The excess oil eventually finds its way to the gear end of the camshaft, over the gears and down the driveshaft housing into a chamber just above the oil pump.

The excess oil thrown off in the crankcase by the connecting rods collects in this same chamber when the engine is inclined so that the propeller end is high. If the propeller end of the engine is low, this oil collects in a small sump or chamber at the propeller end of the crankcase.

Immediately above the oil delivery pump is located an oil return pump consisting of three gears and driven by the same shaft as the delivery pump. The function of this oil return pump is to draw the excess oil out of the crankcase and

return it to the oil reservoir. One section of
this pump draws oil from the sump at the pro-
peller end of the crankcase and the other section
draws oil from the sump at the magneto end of
the crankcase. Both halves of the pump deliver
oil to the connection on the left side of the
oil pump body to be marked "Oil Out" from which
point it returns to the oil reservoir.

(H) Cooling system.

The cooling water is circulated by means of
a centrifugal pump connected through a spline to
the crankshaft gear, and obviously runs at crank-
shaft speed. The housing of the pump is made of
aluminum and the impeller of bronze. As it leaves
the pump the water passes through a pipe leading
under the magneto base on the left side and con-
nections through a hose joint to the cylinder
block.

(I) Propeller Hub.

The new standard hub adopted by the aviation

section of the United States Army is used. The
shaft is given a taper of one in ten, and the
hub is prevented from turning by a straight key
held in place by a flat-headed standard A.S.M.E.
machine screw. The hub is forced in place on
the taper by the long nut by means of a bar put
through the holes at the end of the nut, and
the nut is then prevented from turning by the
pin, which drops into one of the four slots
around the circumference of the nut.

The inner flange is integral with the spool
or barrel of the hub, but the outer flange has
a movement of 1 inch, allowing for hub variations
of from 5 to 6 inches in thickness. The outer
flange is prevented from turning by ten splines;
and as five of these splines are drilled to re-
ceive the locking pin, it gives a large number of
positions in which the nut can be securely locked
in place. This pin is held in position by a wire
running through its head and around the hub, a

groove being provided for this purpose. The
ends are twisted together in the usual way.

The bolts have a taper head to insure a per-
fect fit in the inner flange, and the nut on the
outer end has a projecting sleeve that goes
through the outer flange, so that the thread of the
bolt does not come in contact with the flange at
any point. It will be noticed that the engine
shaft is hollow and that the bolt is drilled for
nearly its entire length. It will also be seen
that the key has a tapped hole at the front end
through which a screw can be used as a jack in
lifting the key out of place, should it become
jammed in any way.

Method of Design and Calculations.

(A) Thermodynamic Analysis.

In the design of this engine it was assumed
that a bore of 5 inches and a stroke of 7 inches
was desired, as is used by the Liberty and Hall
Scott airplane engines. The average compression
ratio was taken as 5 to 1, and the horsepower
rating was to be at the speed of 1750 R.P.M.
Let:

b = bore of cylinder in inches.

L = stroke in inches.

r = compression ratio.

P_1 = initial compression pressure.

P_2 = maximum compression pressure.

V_1 = absolute volume at beginning of com-
pression (piston displacement - clearance
volume)

V_2 = absolute volume at end of compression
(clearance volume)

n = exponent for adiabatic change of state.

From the law of adiabatic change we have:

$$P_1 \, V_1^n = P_2 \, V_2^n = \text{Const.}$$

From which it follows that the compression pressure

$$P_2 = P_1 \left(\frac{V_1}{V_2}\right)^n$$

But $\frac{V_1}{V_2} = r.$

Therefore:

$$P_2 = P_1 \, (r)^n$$

The initial pressure P_1 varies with the piston speed, size and form of passages, and with other factors. At low engine speeds P_1 is generally close to atmospheric pressure but at rated engine speed it drops off so that it is not more than from 12 to 13 pounds per square inch. For a good filling engine we may safely assume that P_1 is 1.5 lbs below atmospheric (i.e $P_1 = 14.7 - 1.5 = 13.2$ lbs per sq. in.) The value of n for compression is an experimental quantity which is found from the actual indicator diagram and may be taken as 1.30. Substituting known values we obtain for

the final compression pressure $P_2 = 13.2 \times (5)^{1.30} =$

106.9 lbs per sq. in.   The explosion pressure

varies with different shapes of combustion chambers

and in this case the ratio may be taken as 4.25 to

1.   We obtain, therefore, as the maximum explosion

pressure,

$$106.9 \times 4.25 = 454. \text{ lbs per sq. in.}$$

The work of expansion as given by Heldt is:

$$W_e = \frac{\pi b^2 a P_2}{14.4} \left(\frac{L}{r-1} \right) \left[1 - \left(\frac{1}{r} \right)^{.32} \right]$$

Where:

    b = bore of cylinder in inches.

    a = ratio of maximum pressure to compression

        pressure.

    P_2 = maximum compression pressure given in lbs

        per sq. in.

    L = length of stroke in inches.

    r = compression ratio.

Substituting the numerical values we obtain:

$$W_e = \frac{\pi \times (5)^2 \times 4.25 \times 106.9}{14.4} \left(\frac{7}{5-1} \right) \left[1 - \left(\frac{1}{5} \right)^{.32} \right]$$

$$= 1744. \text{ foot lbs.}$$

The work of compression as given by Heldt is:

$$W_c = \frac{\pi\, b^2\, P_I}{14.4} \left(\frac{rL}{r-1}\right)\left(r^{0.3} - 1\right)$$

Where P_I = initial compression pressure lb. per sq.

      in.

    Other notation same as before.

Substituting the numerical values we obtain:

$$W_c = \frac{\pi \times (5)^2 \times 13.2}{14.4}\left(\frac{5 \times 7}{5-1}\right)\left(5^{0.3} - 1\right)$$

    = 391. foot lbs.

The useful work per cycle is therefore:

$$W_e - W_c = (1744 - 391.) = 1353.\ \text{foot lbs.}$$

At 1750 R.P.M. there are 875 explosions per minute

and the work done by each cylinder per minute is,

    875 X 1353 = 1,183,875 foot lbs.

One horsepower 33,000 ft. lbs per min. so that

each cylinder develops, $\dfrac{1,183,875}{33000} = 35.9$ Horsepower.

Since the engine has six cylinders, it develops,

    35.9 X 6 = 215.4 Horsepower.

The total M.E.P. on each piston is,

$$\frac{\text{net output of the cylinder}}{\text{stroke of engine in feet}} = \frac{1353}{\left(\frac{7}{12}\right)}$$

= 2320 lbs.

The area of the piston is,

$$\frac{\pi}{4} d^2 = \frac{\pi}{4} (5)^2 = 19.635 \text{ sq. inches.}$$

and the M.E.P. is, therefore,

$$\frac{2320}{19.635} = 118.3 \text{ lbs. per sq. in.}$$

The above analysis is purely theoretical and does not account for the inherent losses prominent in any engine. The values, therefore, in the actual engine are somewhat reduced.

(B) Cylinder Design.

(1.) Clearance volume.

Let:

b = bore of cylinder in inches.

L = length of stroke in inches.

r = compression ratio.

V = piston displacement cu. inches.

C = clearance volume cu. inches.

Then,

$$r = \frac{V + C}{C}$$

or

$$C = \frac{V}{r - 1}$$

But

$$V = \frac{\pi}{4} b^2 L$$

and therefore,

$$C = \frac{\frac{\pi}{4} b^2 L}{r - 1} = \frac{\pi b^2 L}{4(r - 1)}$$

Substituting the numerical values,

$$C = \frac{\pi \times (5)^2 \times 7}{4(5 - 1)} = 34.4 \text{ cu. inches.}$$

The shape of the clearance space and the piston

head are shown in Fig. 1.   The problem now is to

find the height h, , given the piston head dimensions

and the clearance volume.

It can readily be seen from similar triangles

that $h = 1$ inch.

The area of a 5 inch diameter circle is 19.635 sq. in.

The area of a $2\frac{1}{2}$ inch diameter circle is 4.908

sq. in.   The volume of the cone of height h is,

$$\frac{1}{3} \times 19.635 \times 1 = 6.545 \text{ cu. inches.}$$

FIG. 2.
The volume of the small cone is,

$$\frac{1}{3} \times 4.908 \times \frac{1}{2} = .818 \text{ cu. inches.}$$

Therefore the volume of the frustum of the piston

head is, $(6.545 - .818) = 5.727$ cu. inches.

The volume of the cylinder of the same height as

the frustum is, $19.635 \times \frac{1}{2} = 9.8175$ cu. inches.

Therefore the volume represented by the shaded area

of Fig. 1, is, $(9.8175 - 5.727) = 4.0905$ cu. inches

and the difference between the clearance volume

and the volume represented by the shaded area must

equal the volume of height h_1.

Therefore,

$$h_1 = \frac{(34.4 - 4.09)}{19.635} = 1.543 \text{ inches.}$$

The nearest fraction to this is $1\frac{35}{64}$ inches.

The height h_2 is, therefore,

$$1\frac{35}{64} + \frac{1}{2} = 2\frac{3}{64} \text{ inches.}$$

(2.) Thickness of cylinder liner.

The cylinder liner is made of heat treated steel.

A conservative ultimate tensile stress of 60,000

lbs per sq. inch is used for the material. In the

Maybach Aviation engine the safe stress used is 13,280 lbs per sq. in. for the longitudinal seam; and, based on the assumed ultimate stress of 60,000 lbs, the factor of safety is,

$$F = \frac{S_{\mu}}{S_{s}} = \frac{60000}{13280} = 4.52$$

We may assume that the maximum unit pressure in the cylinder is 450 lbs per sq. inch for a compression ratio of 5 to 1.

The equation for the strength of the cylinder in longitudinal tension is,

$$t = \frac{PD}{2S_{t}}$$

Where:

t = thickness of cylinder in inches.

P = unit pressure lb. per sq. in.

D = diameter of cylinder in inches.

S_{t} = safe tensile stress lbs. per sq. in.

Substituting the values,

$$t = \frac{450 \times 5}{2 \times 13,280} = .0847 \text{ inches.}$$

The nearest fraction to this is $\frac{3}{32}$ inch.

The steel liner screws into the aluminum cylinder

block which is $\frac{1}{4}$ inch thick. It is obvious that the aluminum takes some of the stress so that the actual unit stress in the liner is thereby reduced.

Using the practical rule given by Heldt, the width of the water space for engines having bores between 4 and 5 inches, is $\frac{5}{8}$ inch. Foundry practice limits the jacket wall thickness, the smallest practical thickness for aluminum being $\frac{3}{16}$ inch.

(C) <u>Design of Cylinder Bolts.</u>

Four bolts hold the explosion load of each cylinder. The bolts are in direct tension. The total cylinder explosion load at a unit pressure of 450 lbs per sq. in. is,

$$P_i = \frac{\pi}{4} \times (5)^2 \times 450 = 8,836 \text{ lbs.}$$

The load on each bolt is therefore,

$$P = \frac{P_i}{4} = \frac{8836}{4} = 2,209 \text{ lbs.}$$

A safe stress of 15,000 lbs per sq. inch may be used since the bolts are made from .35 carbon-

chrome-nickel steel, heat treated.

Therefore,

$$S_t = \frac{P}{A}$$

From which,

$$A = \frac{P}{S_t} = \frac{2209}{15000} = .1473 \text{ sq. inches.}$$

This is the area required at the bottom of the

thread. From the table of S.A.E. standard screw

threads the nominal diameter of each bolt is $\frac{1}{2}$

inch.

(D) <u>Design of Piston and Piston Rings.</u>

The Liberty type piston was used in this de-

sign and was made 5 inches in length. The width

of the piston rings was made,

$$W = \frac{b}{20} = \frac{5}{20} = \frac{1}{4} \text{ inch.}$$

The thickness opposite the cut was made,

$$t = \frac{b}{24} = \frac{5}{24} = .2085", \text{ say } \frac{3}{16} \text{ inch.}$$

<u>The best location of piston pin.</u> As derived by

Heldt, the equation for the best location of the

piston pin in the piston is given by,

$$X = \frac{5 L^2 + .05 b^2 - .25 bL.}{10 L - b}$$

Where,

>   L = length of piston in inches.

>   X = distance from piston pin axis to head end
>   of piston in inches.

>   b = bore of cylinder in inches.

Substituting numerical values,

$$X = \frac{5 \times (5)^2 + .05 \times (5)^2 - .25 \times 5 \times 5}{(10 \times 5) - 5}$$

   = 2.67 inches, say $2\frac{5}{8}$ inches.

The crown of the piston and a considerable portion

of the skirt is made $\frac{1}{2}$ inch thick, the object being

to facilitate the flow of heat from the head to

the skirt.

(E) Design of Piston Pin.

   The assumed outside diameter taken from the

Liberty motor is $1\frac{1}{4}$ inches.

   The total load on the piston as previously

determined is 8836 lbs at the maximum unit explo-

sion pressure of 450 lbs. Allowing side clearance

of the connecting rod between the piston bosses we

obtain the length of the connecting rod bearing at

the wrist pin which is $2 \frac{3}{8}$ inches.   The projected

area of the bearing is therefore,

   (1.25 X 2.375) = 2.97 sq. inches.

The unit bearing pressure is therefore,

   $\frac{8836}{2.97}$ = 2,980 lbs. per sq. in.

Heldt recommends 2500 lbs per sq. inch and the

Maybach Aviation engine uses 2800 lbs per sq. in.

at 450 lbs explosion pressure.   The value 2980

lbs per sq. inch exceeds the values given but

since the wrist pin is of the full floating type

the bearing pressure is reduced considerably by

the extra bearing area of the piston bushings, so

that the value may be considered a conservative

one.

   The equation for the determination of the

inside diameter of the piston pin is derived by

Heldt and is,

$$d_i = \sqrt[4]{d^4 - \frac{d\,b\,p}{2s}}$$

Where,

   d_i = inside diameter of pin in inches.

d = outside diameter of pin in inches.

b = bore of cylinder in inches.

p = unit explosion pressure lbs per sq. in.

s = safe working stress lbs per sq. in.

The explosion pressure p taken throughout this

design is 450 lbs per sq. inch and the value of s

may be 20,000 lbs per sq. inch for this high grade

steel.

Substituting the numerical values,

$$d_i = \sqrt[4]{(1.25)^4 - \frac{1.25 \times (5)^3 \times 450}{2 \times 20,000}} = .910 \text{ inches,}$$

call it $\frac{15}{16}$ inch.

(F) Design of Crankshaft.

The type used follows standard aviation engine

practice for six and twelve cylinder engines; namely,

the use of seven bearings and hollow bearings and

crankpins.

1. Crankpin diameter and length.

An analysis of a number of six cylinder avia-

tion motors (Benz, Hall Scott, Mercedes, Maybach, etc)

gave an emperical formula for determining the outside

diameter of the crankpin as,

$$d = \sqrt[2]{\frac{D}{34.6}}$$

Where,

    d = outside diameter of crankpin in inches.

    D = piston displacement in cubic inches.

For this engine, the piston displacement is,

$$\frac{\pi}{4} (5)^2 \ X \ 7 = 137.4 \ \text{cubic inches.}$$

The outside diameter of the crankpin is therefore,

$$d = \sqrt[2]{\frac{137.4}{34.6}} = 1.998 \ \text{inches.}$$

    call it 2 inches.

    The explosion load on the crankpin as pre-determined is 8,836 lbs. The bearing pressure for crankpins as given by various authorities is 1800 lbs per sq. inch.

    Using this value we find as the length of the crankpin,

$$L = \frac{p}{1800d} = \frac{8836}{1800 \ X \ 2} = 2.455 \ \text{inches.}$$

    call it 2½ inches.

2. Main journals.

We may assume the thickness of the crank

webs as $\frac{7}{8}$ inch. The center distance between
adjacent cylinders is found to be 6 $\frac{5}{16}$ inches.
The length of each intermediate main journal is
therefore,

$$6 \frac{5}{16} - (2 \text{ X } \frac{7}{8}) - 2 \frac{1}{2} = 2 \frac{1}{16} \text{ inches.}$$

On examination of a number of "<u>six</u>" cylinder
aviation engines it was found that the following
equations hold true,

(1) $T = \dfrac{63025 \text{ H}}{N}$

(2) $S_s = \dfrac{2Ta}{\pi \left(a^4 - b^4\right)}$

Where,

H = brake horsepower of engine

N = R.P.M. of engine.

T = torque in inch. lbs.

S_s = shearing stress next to propeller hub.

a = outside radius of journal inches.

b = inside radius of journal in inches.

The average value of S_s in the engines ex-
amined was 4,000 lbs. per sq. inch. It was found
the better method was to design the journals first

for bearing pressure and then solve by the above
method for the inside diameter of the hollow
journal.

The average value of the journal bearing
pressure was taken as 1000 lbs per sq. inch and
the explosion pressure 450 lbs per sq. inch. Two
journals carry the load on each piston which is
8,836 lbs. Each journal carries,

$$\frac{8836}{2} = 4418 \text{ lbs.}$$

Since the length was found to be $2\frac{1}{16}$ inches
it follows that the diameter based on bearing
pressure must be,

$$\frac{4418}{1000 \text{ X } 2.0625} = 2.14 \text{ inches.}$$

call it $2\frac{3}{16}$ inches.

At the normal horsepower rating of 200 the
torque assumed as constant from equation (1.) is,

$$T = \frac{63,025 \text{ X } 200}{1,750} = 7,200. \text{ inch lbs.}$$

Substituting the known values in equation (2.),

$$\frac{2 \text{ X } 7200 \text{ X } 1.094}{\pi\left[(1.094)^4 - b^4\right]} = 4000$$

and solving,

  $b = .651$ inches.

The inside diameter is,

  $2b = 2 \times .651 = 1.302$ inches.

In the actual design, following Hall Scott six

cylinder practice, the inside diameter of all

journals and crankpins was made $\frac{3}{4}$ inch.

  (3.) <u>Crank cheeks.</u>

  The thickness of the cheeks as before assumed

was $\frac{7}{8}$ inch. For the width, the following equation

was solved for S and this value computed from known

dimensions in a number of six cylinder aviation

engines.

  $$M = S\,\frac{I}{c} = S\,\frac{bh^2}{6}$$

  And $M = \frac{P}{2} R$ since each cheek carries one half

the load.

  $P =$ total load on piston in lbs.

  $R =$ radius of crank in inches.

  $b =$ thickness of cheek in inches.

  $h =$ width of cheek in inches.

The average value of S was found to be 12,500 lbs per sq. inch.

Substituting known values,

$$\frac{8836}{2} \times 3.5 = 12,500 \times \frac{.875\ h^2}{6}$$

And h = 2.91 inches.

Call it $2 \frac{15}{16}$ inches.

(G) <u>Design of Connecting Rod.</u>

    (1.) <u>Design of column.</u>

The connecting rods used are tubular and follow closely the Benz design. The length was taken as 12 inches and the inside diameter of column was taken as $\frac{3}{4}$ of the outside diameter. Using the method given by Heldt, based on the Rankine formula for the strength of columns, we have

$$\frac{P}{0.344\ D^2} + .000526 \frac{P}{0.344\ D^2} \times \frac{L^2}{.0974\ D^2} = S_c$$

Where,

    P = total explosion load on piston in lbs.

    D = outside diameter of rod in inches.

    L = length between centers of rod in inches.

    S_c = safe working stress lb. per sq. inch.

The value of S calculated from the Benz rod was

33,800 lbs per sq. inch, so that,

$$\frac{8836}{0.344\ D^2} + .000526 \times \frac{8836}{0.344\ D^2} \times \frac{(12)^2}{.0974\ D^2} = 33,800$$

solving, we get

$D = 1.112$ inches

Call it $1\frac{1}{8}$ inches.

The inside diameter is therefore,

$\frac{3}{4} \times 1.125 = .844$ inch.

Call it $\frac{27}{32}$ inch.

(2.) Connecting rod bolts.

Four bolts per rod were assumed. The greatest

stress comes on the bolts when the piston starts on

the suction stroke while the motor runs at racing

speed, say, 2000 R.P.M. The force of acceleration

is therefore, (See Heldt P-44, Vol. 1).

$F_a = .0000142\ WLN^2 (\cos \theta + \frac{1}{2n} \cos 2\ \theta)$ lbs.

Where,

W = weight of reciprocating parts in lbs.

$n = \dfrac{\text{connecting rod length (inches)}}{\text{length of stroke (inches)}}$

L = length of stroke in inches.

$N = $ R.P.M.

It is seen that F_a is maximum when $\theta = 0$

Therefore,

$\cos \theta = \cos 2\theta = 1$ when $\theta = 0$ so that the

expression $(\cos \theta + \frac{1}{2n} \cos 2\theta)$ becomes,

$(1 + \frac{1}{2(\frac{12}{7})} \times 1) = 1.292.$

The reciprocating weight W includes the weight of

the piston and rings, the piston pin and one half

the weight of the connecting rod. W for this

engine was estimated as $8\frac{1}{2}$ lbs.

Substituting known values,

$F_a = .0000142 \times 8.5 \times 7 \times (2000)^2 \times 1.292$

$= 4370.$ lbs.

Part of the rod is also rotating and this part is

subject to centrifugal force. The centrifugal

force must be added to the accelerating force.

The rotating weight of the rod was estimated

to be 5.625 lbs. The radius of rotation of this

weight at the moment when the crank is at the top

dead center position was estimated to be 3 inches.

Using the equation for centrifugal force for any

revolving mass,

$$F_c = 1.226 \ WN^2 \ r$$

Where,

W = rotating weight in lbs.

N = revolutions per second.

r = radius of rotation in feet.

We have therefore,

$$F_c = 1.226 \ X \ 5.625 \ X \ \left(\frac{2000}{60}\right)^2 X \ \frac{3}{12}$$

$$= 1915. \ lbs.$$

The total load on the cap bolts is evidently,

$$F_t = F_a + F_c = (4370 + 1915) = 6,285 \ lbs.$$

A safe stress of 20,000 lbs per sq. inch may be

used so that the area at the bottom of the thread

of each bolt is,

$$A = \frac{F_t}{4S} = \frac{6285}{4 \ X \ 20,000} = .0785 \ sq. \ inches.$$

From the bolt table it is found that the nearest

bolt corresponding to the above area has a nominal

diameter of $\frac{3}{8}$ inch.

(H.) <u>Valve and Valve Gear Design.</u>

    (1.) <u>Miscellaneous data concerning valve gear</u>

        <u>design.</u>

The three possible firing orders for six

cylinder engines are:

    1. 1 - 4 - 2 - 6 - 3 - 5

    2. 1 - 5 - 3 - 6 - 2 - 4

    3. 1 - 3 - 2 - 6 - 4 - 5

The firing order chosen is the one used by the

majority of six cylinder aviation engines and is,

        1 - 5 - 3 - 6 - 2 - 4

Cylinder number 1, is nearest the propeller end of

the engine. A six cylinder 4 cycle motor must fire

three times per revolution or every 120 degrees of

crankshaft travel. Since the camshaft travels $\frac{1}{2}$

crankshaft speed the motor must fire every 60 de-

grees of camshaft travel.

The direction of rotation of the engine, facing

the propeller is anti-clockwise. Due to the valve

gear arrangement, the camshaft must travel in the
same direction.

The valve timing was taken from the Liberty
motor and is as follows:

Inlet opens, degrees on crank, 10° Late.

Inlet closes, " " " , 45° Late.

Exhaust opens, " " " , 50° Early,

Exhaust closes, " " " , 10° Late.

Ignition, magnetos fully advance, 30° Early.

Ignition, magnetos fully retarded, 10° Late.

The inlet valve is therefore open for a
period of 215 degrees of crankshaft travel, or
107 $\frac{1}{2}$ degrees of camshaft travel.

The exhaust valve is open for a period of 240
degrees of crankshaft travel or 120 degrees of cam-
shaft travel. The compression period with spark
advanced is 105 degrees crankshaft travel and with
spark retarded is 145 degrees crankshaft travel.
The expansion period with spark advanced is 160 de-
grees of crankshaft travel and with spark retarded
is 120 degrees of crankshaft travel.

(2.) <u>Valve design.</u>

From the law of continuity of flow,

$$A_P V_P = A_v V_G$$

Where,

A_P = area of piston in sq. inches.

A_v = area of clear opening of valve in inches.

V_P = maximum piston velocity ft. per minute.

V_g = velocity of gas through valve ft. per minute.

Now $A_P = \dfrac{\pi}{4} b^2$

and $A_v = \dfrac{\pi}{4} d^2$

where b and d are the diameters of the cylinder and valve respectively.

Therefore,

$$\frac{\pi}{4} b^2 V_P = \frac{\pi}{4} d^2 V_g$$

And,

$$d = b^2 \sqrt{\frac{V_P}{V_g}}$$

The maximum piston velocity is given by,

$$V_P = 2 L n.$$

Where,

L = length of stroke in feet.

n = revolutions per minute.

Therefore,

$$V_P = 2 \times \frac{7}{12} \times 1750 = 2040 \text{ ft. per minute.}$$

The value of V_g ranges from 7000 to 9000 ft. per minute. Using 9000 for V_g we obtain,

$$d = 5\sqrt[2]{\frac{2040}{9000}} = 2.37 \text{ inches.}$$

From the layout it was found that the largest valve that can be placed in this type of cylinder was $2\frac{1}{8}$ inches clear diameter. The general dimensions of the valve was taken from practice for engines of this size.

The equation for valve lift was taken from Heldt and agrees closely with practice,

$$h = \frac{d}{8} + \frac{1}{8} \text{ inch.}$$

Where h = lift in inches.

d = clear diameter of valve in inches.

Therefore:

$$h = \frac{2.125}{8} + \frac{1}{8} = .39 \text{ inch.}$$

Call it $\frac{3}{8}$ inch.

(3.) Camshaft design.

The type used is of hollow construction having mushroom cams acting directly on the valve stem discs.

The outside diameter was taken as $1 \frac{3}{8}$ inch.

Let:

D = center distance between base and top circles of intake and exhaust cams, in inches.

R = radius of base circle in inches.

C = clearance in inches.

r = radius of top circle in inches.

L = lift of valve in inches.

R was taken as $\frac{3}{4}$ inch and r assumed to be $\frac{1}{16}$ inch. The clearance used on both cams was .02 inch.

Then,

$$D = R + C + L - r$$

or

$$D = .75 + .02 + .375 - .0625$$

$$= 1.0825 \text{ inches.}$$

The method of laying out this type of cam is described as follows: (See Fig. 2)

Draw the base circle and top circle, the radii of which have been assumed. The two centers are placed at a distance D apart, as given above. Lay off the clearance circle C outside the base circle. Lay off from the center line connecting the two centers, an angle equal to $\frac{1}{2}$ the valve period. Let this line intersect the clearance circle at the point P. From P draw a tangent T to the clearance circle. Now draw an arc A which is tangent to the base circle, the top circle and the tangent T to the clearance circle. If the arc A becomes straight the radii R and r must be changed.

Drawing #17 shows the valve lift diagrams for both the inlet and exhaust cams. The curves were plotted directly from the cam layout given on drawing number 9.

The advantage in using the mushroom type cam is that the valve accelerates very quickly at the

FIG. 2.

beginning of the lift. As compared with the tangential and constant acceleration cams it ranks first in quick opening; but the steepness at the beginning of the lift curve is a measure of the blow dealt the cam follower by the cam when first coming in contact with it. On comparing the lift diagrams of the mushroom, tangential and constant acceleration cams it can be seen that the mushroom type cam crosses the clearance line by far the greatest angle, consequently this cam would be expected to be the most noisy. However, in the mushroom cam the speed of lift at the beginning exceeds that of the other two cams, hence the volumetric efficiency would be expected to be greatest with that type of cam. From a standpoint of strength of valve spring required the mushroom cam ranks first in merit.

From drawing #17, it can be seen that the valve accelerates to the point A and from there to full lift it is retarded. It is also evident that the

lift curve is a time-space curve. Thus, we may
use the abscissae as time in seconds, since the
crankshaft travel in degrees is a function of
the time; and the ordinates as feet, by dividing
the lift in inches by 12.

A tangent to the time-space curve will give
the instantaneous velocity in feet per second at
that particular point, since by definition,
$v = \tan\alpha = \frac{ds}{dt}$ also, by definition, the instan-
taneous acceleration is given by, $a = \tan\beta = \frac{dv}{dt}$
$= \frac{d^2 s}{dt^2}$ and therefore a tangent to the velocity
curve would give the instantaneous acceleration
of the valve, in feet per second, per second.
Note: Acceleration always given in <u>feet per second</u>,
<u>per second.</u>

(3.-A) <u>Dimensions of camshaft.</u>

The camshaft must be stiff, well supported
and have very little deflection under the valve
load. When the cam is just at the point of lift-
ing the valve, the latter receives a shock due to

impact and this is, of course, greatest in the
case of the exhaust valve. The exhaust valve
must be lifted against the force due to inertia
of the valve, combined with the initial spring
pressure and the pressure of the gases in the
cylinder near the end of the expansion stroke. The
latter pressure according to Heldt is 50 lbs. per
sq. inch.

In the case of the inlet valve only the inertia
of the valve and the spring tension need be con-
sidered, as the valve does not have to be lifted
against a pressure. According to Heldt the force
required to lift the exhaust valve is approximately
75 lbs. per sq. inch of valve area.

Referring to Fig. 3,

Let

L = distance between adjacent bearings.

xL = distance of the centre of the cam from
the farthest bearing.

P = load on cam in lbs.
FIG. 3.

E = coefficient of elasticity.

I = moment of inertia of section of shaft.

Then, the deflection of the shaft at the centre of the cam under the total load P will be

$$y = \frac{PL^3}{6EI} (2x^4 + 2x^2 - 4x^3)$$

$$\text{or } I = \frac{PL^3}{6Ey} (2x^4 + 2x^2 - 4x^3)$$

From the layout we have,

L = 12.625 inches.

xL = 10.6875 inches.

And therefore, x = .8475.

From the table given by Heldt (Page 279) we find for the value of x = .85 that $(2x^4 + 2x^2 - 4x^3)$ = .033.

The deflection, y, should not exceed .002 inch.

$$P = \frac{\pi}{4}(2\tfrac{1}{8})^2 \times 75 = 266 \text{ lbs for the exhaust valve.}$$

Therefore,

$$I = \frac{266 \times (12.625)^3 \times .033}{6 \times 30,000,000 \times .002}$$

$$= .0490$$

This is the required moment of inertia determined

by the exhaust valve.

For the inlet valve, assume the maximum P equal to twice the mean spring pressure or,

$P = 2 \times 70 = 140$ lbs.

$L = 12.625$

$xL = 8.1875$

and $x = .649$

From the table, $(2x^4 + 2x^2 - 4x^3) = .104$.

Therefore,

$$I = \frac{140 \times (12.625)^3 \times .104}{6 \times 30,000,000 \times .002} = .0815$$

This is the required moment of inertia determined by the inlet valve. It is seen that the inlet cam determines the size of the camshaft rather than the exhaust cam, in this case.

The moment of inertia of a hollow shaft is given by,

$$I = \frac{\pi}{64}\left[D^4 - d^4\right] = .0491\left[D^4 - d^4\right]$$

Where,

D = outside diameter of shaft in inches.

d = inside diameter of shaft in inches.

Since we assumed that D was $1\frac{3}{8}$ inch and found the
value of I to be .0815 we find that,

$$d = \sqrt[4]{D^4 - \frac{I}{.0491}} = \sqrt[4]{(1.375)^4 - (\frac{.0815}{.0491})}$$

$$= 1.18 \text{ inches.}$$

The largest practical dimension that can be used is $1\frac{1}{8}$ inches. As a comparison it might be stated that the Hispano Suiza Aviation engine has a camshaft, 34 m/m outside diameter and 28 m/m inside diameter.

The shell thickness is therefore 3 m/m or .118 inch as compared to $\frac{1}{8}$ inch for this design.

(4.) <u>Valve spring design.</u>

The equations used in the calculation of valve springs are:

$$1. \quad W = \pi \frac{Sd^3}{8D}$$

$$2. \quad F = \frac{8n \ PD^3}{Ed^4}$$

Where:

D = mean diameter of coil in inches.

W = maximum safe load in lbs.

F = compression of spring in inches.

d = diameter of wire in inches.

n = number of coils in spring.

S = maximum safe fibre stress of material lbs per sq. inch.

E = torsional modulus of elasticity.

P = load in lbs.

We may assume E as 12,000,000 and S as 50,000 lbs. per sq. inch. The lift of the valve is $\frac{3}{8}$ inch and the mean diameter of the spring was taken as 1 $\frac{23}{32}$ inches. The spring is to be designed so that it exerts 60 lbs. pressure when the valve is closed and 76 lbs when fully lifted. Since the lift of the valve is $\frac{3}{8}$ inch, 16 lbs pressure compresses the spring $\frac{3}{8}$ inch.

The necessary diameter of wire is found from equation (1.),

$$76 = \frac{\pi \times 50,000 \times d^3}{8 \times 1.719}$$

And d = 0.188 inch.

This is approximately the diameter of a No. 7 (Birmingham gauge) steel wire. The actual diameter is .180 inch.

Using equation (2.) we find,

$$\frac{3}{8} = \frac{8 \times n \times 16 \times (1.719)}{12,000,000 \times (.180)^4}$$

and

n = 7 coils (approx)

The design was somewhat changed in that d was made No. 9 GA. and n was made 8. When the spring is compressed there is sufficient space between coils so that they do not come together.

(5.) <u>Gear design.</u>

The pitch diameters of gears chosen are as follows,

Camshaft gear - 5 $\frac{1}{4}$ inches.

Upper vertical shaft gear - 1 $\frac{3}{4}$ inches.

Lower vertical shaft gear - 3 inches.

Crankshaft gear - 4 $\frac{1}{2}$ inches.

Magneto gears - 1 $\frac{3}{4}$ inches.

By taking moments and using the maximum load on cam as before determined we find that the camshaft gear tooth load is 116 lbs. Using equation 1, Page 112 of Nachman's Machine Design,

$$P = \frac{16.8\ W}{S\ b}$$

Where

W = load on tooth in lbs.

S = safe working stress.

b = face of gear in inches.

P = circular pitch of gear in inches.

b for all the drive gears except magneto gears was made $\frac{1}{2}$ inch and S may be taken as 15,000 lbs per sq. inch for this alloy steel.

Therefore,

$$P = \frac{16.8 \times 116}{15000 \times .5} = .260 \text{ inch.}$$

The pitch circumference of the camshaft gear is 16.4934 inches. Therefore the number of teeth is, $\frac{16.4934}{.260} = 63.5$

say 63 teeth.

The upper vertical shaft gear therefore has 21 teeth. This corresponds to a diametral pitch of, $\frac{63}{5.25} = 12.$ 12 - 14 pitch stub tooth gears were used. The lower gear set was calculated in identically the same manner and the results are,

Lower vertical shaft gear - 30 teeth.

Crankshaft gear - 45 teeth.

Diametral pitch - 10

10 - 12 pitch stub tooth gears were used. The reason for making the lower gears larger in diametral pitch than the upper set is due to the fact that they operate the oil pump, in addition to the vertical shaft.

(6.) <u>Design of vertical shaft.</u>

This shaft is of hollow construction with the upper vertical drive gear integral.

The maximum torque transmitted by the shaft is small since it runs at 1.5 crankshaft speed.

The torque is:

$$T = PR$$

Where:

P = tooth pressure on upper gear.

R = pitch radius of gear in inches.

Then, $T = 116 \times \dfrac{1.75}{2} = 101.5$ inch lbs.

For a hollow circular shaft of outside radius a,

and inside radius b,

$$S_S = \frac{2\,Ta}{\pi\,(a^4 - b^4)}$$

and,

$$b = \sqrt[4]{a^4 - \frac{2\,Ta}{\pi\,S_S}}$$

The outside diameter was assumed as $\frac{7}{8}$ inch so that $a = \frac{.875}{2} = .4375$ inch.

The safe working stress may be taken as 10,000 lbs per sq. inch.

Hence,

$$b = \sqrt[4]{(.4375)^4 - \frac{2 \times 101.5 \times .4375}{\pi \times 10000}}$$

$$= .428 \text{ inch.}$$

The inside diameter is therefore .856 inch. It is obvious that this shaft is under a feeble stress and one of practical dimensions must be chosen. The inside diameter was made $\frac{11}{16}$ inch.

(7.) <u>Valve timing adjustment.</u>

After assembly it is necessary to time the engine due to side play in the bevel gear train. The usual method is by means of a timing disc placed over the crankshaft at the propeller end.

Place the engine at the upper dead center of
cylinder number 1, nearest the propeller end and
mount the timing disc on the taper of the crank-
shaft. Turn the engine in the running direction
10 degrees, (Position where the inlet opens and
exhaust closes of cylinder number 1) and put the
camshaft in place, the closing of the exhaust cam
and opening of the inlet valve cam making the same
angle in relation to the valve adjustment mush-
rooms of cylinder number 1. Tighten the nuts on
the four bearings and adjust the proper valve
clearance. Turn the crankshaft slowly backward,
then gently rotate forward, feeling the exhaust
valve which should close 10 degrees after dead
center, while at the same time the inlet valve
should begin to unseat.

If the timing is not accurate, it is necessary
to take the camshaft gear off for the sake of
shifting splines, or in turning the vertical shaft,
to give the following:

There are 63 teeth in gear and 21 in pinion,

8 spline keys in gear and 5 in pinion shaft.

1 tooth of camshaft gear = 2.857 degrees of cam-
shaft travel or 5.714 degrees of crankshaft travel.

1. Rotate gear clockwise 1 spline key and
pinion clockwise $\frac{1}{4}$ tooth to give $\frac{1}{4}$ tooth on cam-
shaft gear advance.

2. Rotate gear clockwise 2 spline keys and
pinion clockwise $\frac{1}{2}$ tooth to give $\frac{1}{2}$ tooth advance.

3. Rotate gear clockwise 3 spline keys and
pinion clockwise $\frac{3}{4}$ tooth to give $\frac{3}{4}$ tooth advance.

4. Rotate gear clockwise 4 splines and pinion
clockwise 1 tooth to give 1 tooth advance.

5. Rotate gear clockwise 2 splines and pinion
clockwise $\frac{1}{2}$ tooth to give $\frac{1}{2}$ tooth advance. Now
rotate pinion counterclockwise one spline to give
$\frac{1}{10}$ tooth advance.

6. Rotate gear counterclockwise one spline
and pinion counterclockwise $\frac{1}{4}$ tooth to give $\frac{1}{4}$
tooth retard. Now rotate pinion clockwise one

spline to give $\frac{3}{20}$ tooth advance.

By reversing each step of the above, we may obtain exactly the same values for retard. It is seen that we have a range of adjustment, either advance or retard, from a whole tooth to one tenth tooth of the camshaft gear. Of course, this must be multiplied by 2 to find actual crankshaft degrees.

(I.) General Crankcase Design.

The crankcase does not lend itself well to mathematical treatment, but must be designed by the use of good engineering judgement. The chief stresses to which a crankcase is subjected are:

1. Stress in crankcase bosses due to explosion reaction.

2. Stress in supporting arms and parts intermediate between the cylinder flanges and arms due to torque reaction.

3. Stress in arms and entire case due to weaving of the frame.

The thickness of the metal (aluminum) around the cylinder openings (according to Heldt) was made $\frac{1}{8}$ inch per inch of cylinder bore or $\frac{5}{8}$ inch. The average thickness of the case is $\frac{1}{4}$ inch. The case was reenforced with $\frac{3}{8}$ inch webs on the inside.

(J.) Oil Pump Design.

The oil pump is of the gear-force feed type. Heldt gives the rule to supply 25 cubic inches of oil per minute per square inch of projected crankshaft bearing surface at the maximum speed of the motor.

The projected area for this engine is 68 sq. inches including crankpins. Therefore the pressure pump should move 68 X 25 = 1700 cu. inches of oil per minute at a crankshaft speed of 1750 R.P.M.

Let

   d = pitch diameter of one of the pump gears.

   P = diametral pitch.

   h = height of teeth = $\frac{2}{P}$

   f = width of face of gears.

n = revolutions per minute of gears.

Q = quantity of oil delivered in cubic inches
per minute.

Then according to Heldt,

$$Q = \frac{2\pi \, d \, f \, n}{P}$$

and therefore,

$$P = \frac{2\pi \, d \, f \, n}{Q}$$

Assume that $d = 1\frac{1}{4}$ inches and that $f = \frac{3}{4}$ inch for the feed gears. Since the oil pump runs at 1.5 engine speed it makes 2625 turns per minute. Therefore:

$$P = \frac{2\pi \times 1.25 \times .75 \times 2625}{1700} = 9.08$$

P was made 8 so that the number of teeth was 1.25 X 8 = 10. The oil return gears were made identical to the pressure gears except the width of face f was made 1 inch.

(K.) Water Pump.

The water pump is of the Liberty type with one outlet. The diameter of the rotor was found from, $D = .85\sqrt[4]{V}$

Where,

    V = total piston displacement of engine in

    cubic inches.

Therefore,

$$D = .85 \sqrt{19.635 \times 7 \times 6} = 4.55 \text{ inches.}$$

    Call it 4 $\frac{1}{2}$ inches.

CONCLUSION.

In concluding the present work the writers
wish to emphasize both the special features of con-
struction and the criticism of their results. The
salient features of design are stated briefly as
follows:

(1) Hollow-stem valves with adjustable tappets,
which provides for the direct action of the cam
upon the tappet, thereby eliminating the use of
rocker arms, push-rods etc.

(2) Overhead hollow camshaft supported by four
bronze bushings driven from the crankshaft by means
of a vertical shaft and bevel gears.

(3) Lower vertical drive provided with ball
bearings for the reduction of friction.

(4) Magneto bases cast integral with upper
crankcase allowing compact construction.

(5) Light cylinder construction made possible
through the use of an aluminum jacket and steel
sleeves.

(6) Aluminum alloy pistons using spring rings to lock piston pin.

(7) Tubular connecting rods allowing increased strength with reduction in weight.

(8) Seven bearing hollow crankshaft.

(9) Aluminum alloy crankcase with the main crankshaft bearings supported in both the upper and lower halves. Long bolts passing through both halves of crankcase. Cylinders held in position by triangular bridge clamps, a design which adds to the stiffness of the crankcase construction.

(10) Forced feed lubrication using the dry sump proposition.

(11) Two "Dixie" magnetos firing two plugs per cylinder a prevention against misfiring due to fouled spark plugs. The following are the criticisms offered by the writers:

(1) Owing to the accurate machine work which must be performed on the cylinder, the cost of production is against this particular design. As a

commercial engine, therefore, the cylinder design would not be favored.

(2) The crankshaft main bearings cannot be adjusted, a point contrary to the design. As is seen from the drawings that should a bushing become worn it must be replaced with a new one. The joint between the two halves of the case must be lapped using this construction - an expensive operation. However, the Liberty and Hispano-Suiza designs favor this construction. The oil film is not broken and this, no doubt is the reason for its use in the above engines.

(3) As is previously stated, the propeller hub was taken from the United States Army Aviation Standards. This hub appears to be rather heavy and by extended study could, no doubt, be reduced in weight.

The following suggestions may be considered should the motor be redesigned:

(1) Integral construction of aluminum cylinder block and upper crankcase, the steel cylinder liners

being pressed into place. This construction calls

for a detachable cylinder head with cast iron

valve seats cast in the head. Using this construc-

tion of cylinder and crankcase, the steel sleeves

may be obviated by electroplating a thin coat of

iron directly on the aluminum wall. This construc-

tion has been used on a small air cooled motor and

is a matter of future development.

(2) The use of steel crankshaft bearing caps

in place of the construction used in the present

design.

(3) The use of sliding vane oil pumps.
